ABSTRACT

We present an analysis of both the resolved X-ray emission-line profiles and the broad-band X-ray spectrum of the O2 If∗ star HD 93129A, measured with the Chandra High Energy Transmission Grating Spectrometer (HETGS). This star is among the earliest and most massive stars in the Galaxy, and provides a test of the embedded wind-shock scenario in a very dense and powerful wind. A major new result is that continuum absorption by the dense wind is the primary cause of the hardness of the observed X-ray spectrum, while intrinsically hard emission from colliding wind shocks contributes less than 10 per cent of the X-ray flux. We find results consistent with the predictions of numerical simulations of the line-driving instability, including line broadening indicating an onset radius of X-ray emission of several tenths of $R_\ast$. Helium-like forbidden-to-intercombination line ratios are consistent with this onset radius, and inconsistent with being formed in a wind-collision interface with the star’s closest visual companion at a distance of 100 au. The broad-band X-ray spectrum is fitted with a dominant emission temperature of just $kT = 0.6$ keV along with significant wind absorption. The broad-band wind absorption and the line profiles provide two independent measurements of the wind mass-loss rate: $\dot{M} = 5.2^{+1.8}_{-1.3} \times 10^{-6}$ and $6.8^{+2.8}_{-2.2} \times 10^{-6} M_\odot$ yr$^{-1}$, respectively. This is the first consistent modelling of the X-ray line-profile shapes and broad-band X-ray spectral energy distribution in a massive star, and represents a reduction of a factor of 3–4 compared to the standard Hα mass-loss rate that assumes a smooth wind.

Key words: stars: early-type – stars: individual: HD 93129A – stars: mass-loss – stars: winds, outflows – X-rays: stars.

1 INTRODUCTION

With a spectral type of O2 If∗ (Walborn et al. 2002), HD 93129A is among the earliest, hottest, most massive and luminous O stars in the Galaxy. As such, it has an extremely powerful wind, with a terminal velocity in excess of 3000 km s$^{-1}$, and a mass-loss rate thought to be in excess of $10^{-5}$ $M_\odot$ yr$^{-1}$ (Repolust, Puls & Herrero 2004). In fact, HD 93129A has been considered to have the highest mass-loss rate of any O star in the Galaxy (Taresch et al. 1997; Benaglia & Koribalski 2004). This star, therefore, provides an interesting test of the wind-shock paradigm of massive star X-ray emission, both because of the tremendous kinetic power in its wind

and because of the dominant role played by X-ray absorption in such a dense wind. In order to study the X-ray emission and absorption, we have analysed the Chandra High Energy Transmission Grating Spectrometer (HETGS) spectrum with a focus on individual line profiles. In addition, we analyse the low-resolution, zeroth-order Advanced CCD Imaging Spectrometer (ACIS) CCD spectrum in order to determine the relative contributions of high-temperature thermal emission and wind attenuation to the observed spectral hardness. These complementary analysis techniques provide information about the temperature and kinematics of the X-ray-emitting plasma, about its spatial distribution and about the wind mass-loss rate.

X-ray emission from O stars is attributed to three mechanisms: (1) embedded wind shocks (EWSs), generally assumed to be associated with the line-driving instability (LDI; Lucy & White 1980;
In this paper we refer to ‘optically thin clumping’ when discussing clumps of H\emissionstrength. The associated clumping factors are consistent with other recent \(\alpha\) emission under the assumption of a smooth, roughly a factor of 3 lower than the traditional value derived from opacity (Cohen et al. 2010). The initial application of this technique characterizes optical depths, given a model of the bulk wind X-ray emission lines from EWSs have a characteristic blueshifted and shifted line photons from the far hemisphere of O star winds, X-ray EWS scenario. Furthermore, due to preferential absorption of red-shifted line photons from the hot hemisphere of O star winds, X-ray emission lines from EWSs have a characteristic blueshifted and skewed shape, in proportion to the characteristic wind optical depth (Owocki & Cohen 2001). It has recently been shown that a wind mass-loss rate can be determined by setting the ensemble of derived characteristic optical depths, given a model of the bulk wind X-ray opacity (Cohen et al. 2010). The initial application of this technique to \(\zeta\) Pup (O4 If) provided a mass-loss rate determination that was roughly a factor of 3 lower than the traditional value derived from the strength of the H\alpha emission under the assumption of a smooth, unclumped wind. This lower value is consistent with other recent reassessments (Puls et al. 2006) that do account for small-scale wind clumping, which affects density-squared diagnostics such as H\alpha emission strength. The associated clumping factors are consistent with those seen in numerical simulations of the LDI (Runacres & Owocki 2002; Dessart & Owocki 2005). Indeed, there is a consensus emerging that many, if not all, O stars’ mass-loss rates must be lowered by factors of several due to the effects of clumping (Hamann, Feldmeier & Oskinova 2008). In this context, the X-ray line-profile mass-loss rate diagnostic is especially useful, as it is not affected by small-scale clumping, as long as the individual clumps are optically thin to X-rays (Cohen et al. 2010).

Both numerical simulations and the lack of significant observed X-ray variability indicate that clumps in O star winds are on quite small scales, with sizes \(\ell \ll R_\star\). Since even the entire wind of HD 93129A is only marginally optically thick to bound-free absorption of X-rays, it is very likely that such small clumps will be individually quite optically thin to X-rays. This means that the 

\(\beta\) \(M\) \(M_\odot\) \(M_\odot\ yr^{-1}\) 
\(1.8 \times 10^{-5}\) \(3200\) \(6.4 \times 10^{-1}\) \(19.7\) \(3200\) \(5.2 \times 10^{-1}\) \(3.7 \times 10^{21}\) \(1.7 \times 10^{-1}\) \(0.7\) \(0.6\) \(6.17\) \(10^{21}\) \(10^{21}\) \(52000\) \(22.5\) \(6.61\) \(130\) \(10^{-1}\) \(10^{-5}\) 

This table shows the stellar and wind parameters adopted from Taresch et al. (1997) and Repolust et al. (2004) (in parentheses).
quantities. Given that the companion is about a magnitude dimmer than the primary, this effect will be small (Repolust et al. 2004).

We describe the Chandra HETGS data in Section 2. In Section 3 we analyse the line profiles seen in the grating spectrum and also fit global thermal emission models to the low-resolution but higher signal-to-noise ratio zeroth-order spectrum. We discuss the implications of these analyses for the three mechanisms of O star X-ray emission in Section 4, and summarize our conclusions in Section 5.

2 THE Chandra DATA

The data we use in this paper were taken between 2005 November 8 and December 5 in seven separate pointings, with a total effective exposure time of 137.7 ks. All observations employed the ACIS with the HETGS (ACIS-S/HETGS; Canizares et al. 2005), providing dispersed spectra in the medium energy grating (MEG) and high energy grating (HEG) arrays, as well as a low-resolution CCD spectrum from the zeroth-order image. The grating data have been presented previously in Westbrook et al. (2008) and Walborn (2008).

The field is crowded with X-ray sources, but only HD 93129B, our target’s visual companion, is bright enough and close enough to HD 93129A to pose a potential problem in the data extraction. In Fig. 1 we show the centre of the ACIS detector for the longest of the seven separate exposures, with the MEG and HEG extraction regions indicated, and the zeroth-order images of components A and B labelled. The CCDs that compose the ACIS detector have modest intrinsic energy resolution (of roughly $E/\Delta E = 20–50$), allowing us to assess the spectral energy distribution of each source as indicated by the colour coding in the figure. For this particular exposure, component B, which is 2.7 arcsec south-east of component A, lies in the MEG and HEG extraction regions, and therefore is a potential source of contamination of the dispersed spectra of component A.

Due to the varying roll angle of the Chandra instrument, component B does not lie fully in the extraction regions of component A for all of the seven separate observations. Furthermore, as shown in Fig. 2, its photon flux is an order of magnitude lower than that of component A. Finally, the spectral energy distribution of component B is much softer than that of component A (this can also be seen, qualitatively, in the colour coding of Fig. 1). In fact, there are almost no counts from component B at energies greater than 1.2 keV, corresponding to a wavelength of 10 Å. Thus, the dispersed spectra of component A are unaffected by contamination from component B below this wavelength. At wavelengths above 10 Å, however, there is likely to be modest contamination. We note that the 2.7-arcsec offset corresponds to a relative shift in the dispersed MEG spectrum of roughly 1500 km s$^{-1}$, which could artificially broaden the emission lines of component A. We therefore restrict the analysis of the grating spectra in this paper to wavelengths shortwards of 10 Å.

We note also that the close binary companion Ab detected at 0.05 arcsec with the FGS is completely unresolved by Chandra, so the spectra we analyse in this paper are a composite of the two components. However, the spectral type of Ab is tentatively identified as being the same as that of component B (O3.5 V) (Nelan et al. 2004), so the composite spectrum, especially below 10 Å, is likely dominated by component Aa. We discuss the colliding wind X-ray emission due to this close visual companion in Section 3.3.

After centroiding the zeroth-order image of component A in each of the seven separate exposures, we co-added the observations, with the MEG and HEG extraction regions indicated, and the zeroth-order images of components A and B labelled. The CCDs that compose the ACIS detector have modest intrinsic energy resolution (of roughly $E/\Delta E = 20–50$), allowing us to assess the spectral energy distribution of each source as indicated by the colour coding in the figure. For this particular exposure, component B, which is 2.7 arcsec south-east of component A, lies in the MEG and HEG extraction regions, and therefore is a potential source of contamination of the dispersed spectra of component A.

Due to the varying roll angle of the Chandra instrument, component B does not lie fully in the extraction regions of component A for all of the seven separate observations. Furthermore, as shown in Fig. 2, its photon flux is an order of magnitude lower than that of component A. Finally, the spectral energy distribution of component B is much softer than that of component A (this can also be seen, qualitatively, in the colour coding of Fig. 1). In fact, there are almost no counts from component B at energies greater than 1.2 keV, corresponding to a wavelength of 10 Å. Thus, the dispersed spectra of component A are unaffected by contamination from component B below this wavelength. At wavelengths above 10 Å, however, there is likely to be modest contamination. We note that the 2.7-arcsec offset corresponds to a relative shift in the dispersed MEG spectrum of roughly 1500 km s$^{-1}$, which could artificially broaden the emission lines of component A. We therefore restrict the analysis of the grating spectra in this paper to wavelengths shortwards of 10 Å.

We note also that the close binary companion Ab detected at 0.05 arcsec with the FGS is completely unresolved by Chandra, so the spectra we analyse in this paper are a composite of the two components. However, the spectral type of Ab is tentatively identified as being the same as that of component B (O3.5 V) (Nelan et al. 2004), so the composite spectrum, especially below 10 Å, is likely dominated by component Aa. We discuss the colliding wind X-ray emission due to this close visual companion in Section 3.3.

After centroiding the zeroth-order image of component A in each of the seven separate exposures, we co-added the observations and extracted the first-order MEG and HEG spectra, as well as the zeroth-order ACIS CCD spectrum shown in Fig. 2. The co-added negative and positive first-order spectra (both MEG and HEG) are shown in Fig. 3. The MEG spectrum has a full width at half-maximum resolution of 2.3 mÅ and the HEG, with a lower sensitivity, has a resolution of 1.2 mÅ. In the 5–10 Å region where most of the counts are, these correspond to resolving powers of roughly $\lambda/\Delta \lambda = 300–600$ in the MEG.

Even with the co-addition of seven separate pointings, for an effective exposure time of 137.7 ks, the spectra have quite low signal-to-noise ratio. This is due both to the great distance to HD 93129 (2.3 kpc) and to the large interstellar column density, which causes significant attenuation of the soft X-ray emission from the star. As we will show in Section 3, there is also significant X-ray attenuation from the dense stellar wind. The appearance of the Chandra grating spectra of HD 93129A is certainly significantly harder than that of other normal O stars, but this is due primarily to attenuation and not to high temperatures, as can be seen qualitatively in Fig. 3 from the dominance of the H-like lines (SiXIII, MgXI) over the corresponding H-like lines (SiXIV, MgXII), especially for silicon. This qualitative impression is borne out by quantitative modelling presented in Section 3.3.

Only a handful of lines are present in the MEG spectrum (and even fewer in the lower signal-to-noise ratio HEG spectrum). The...
The small number of visible lines is affected by the overall low signal-to-noise ratio and the aforementioned attenuation, which renders the normally quite strong Fe XVII and O lines longwards of 15 Å completely absent, and it is exacerbated by the very large linewidths, which spread the modest number of line photons over many pixels. After discarding the very weak lines longwards of 10 Å due to contamination from component B, we are left with five lines and blended line complexes detected with greater than 3σ significance: the He-like SXV complex near 5.1 Å, the Lyα line of Si XIV at 6.18 Å, the He-like Si XIII complex near 6.7 Å, the Mg XII Lyα line at 8.42 Å and the He-like Mg XI complex near 9.2 Å. The weak Mg XI Heβ line at 7.85 Å is not detected above the 3σ threshold. Not shown in the figure are very weak Ne IX and Ne X lines between 12 and 14 Å, which are affected by contamination from the softer X-ray emission from component B, as discussed above.

### 3 SPECTRAL ANALYSIS

#### 3.1 Resolved emission lines

By fitting a simple, empirical line-profile model (Owocki & Cohen 2001) to the Doppler-broadened emission lines, we can simultaneously determine the kinematics of the X-ray-emitting plasma and the degree of attenuation by the wind in which the hot, shock-heated plasma is embedded. The specific parameters of the Owocki & Cohen (2001) model are the onset radius of the X-ray emission ($R_o$) and the fiducial optical depth of the bulk wind, $\tau_\star \equiv \kappa \dot{M}/4\pi R_*/v_\infty$. Note that $\tau_\star$ is expected to vary from line to line due to the wavelength dependence of the wind opacity, $\kappa$.

The fitted $R_o$ values derived from the data are expected to be several tenths of a stellar radius above the photosphere, based on simulations of the LDI (Owocki et al. 1988; Feldmeier et al. 1997; Runacres & Owocki 2002). By deriving values for this parameter from the individual lines in the Chandra spectrum of HD 93129A, we can test the LDI scenario for EWSs in the most extreme O star wind. And the values we derive for the fiducial optical depth, $\tau_\star$, can be used to derive a mass-loss rate by fitting the ensemble of values, given a model of the wind opacity, as has been shown by Cohen et al. (2010).

Following the procedure described in Cohen et al. (2010), we assess the continuum level near each line by fitting a small region of the spectrum on either side of the line, and then fit a profile model plus the continuum model (with the level fixed at the value found from fitting the nearby continuum). We allow the normalization, $R_o$, and $\tau_\star$ to be free parameters of the fit, while fixing the velocity law parameter at $\beta = 0.7$ (Taresch et al. 1997) and the terminal velocity at the value determined from the analysis of UV observations, $v_\infty = 3200 \text{ km s}^{-1}$ (Taresch et al. 1997; Repolust et al. 2004). We find the best-fitting model parameters by minimizing the C statistic (Cash 1979), and assign confidence limits individually to each model parameter (while allowing the other free parameters to vary) according to the formalism in Press et al. (2007). We fit the MEG...
and HEG data simultaneously. We perform all of this modelling and
data analysis in XSPEC v.12.6, using the custom model windprof.2

For the helium-like complexes, which effectively comprise three
blended lines each [resonance (r), intercombination (i) and
forbidden (f)], we fit three profile models simultaneously (using
the custom model hewind), with the $R_0$ and $\tau_*$ parameters tied together
for each of the three lines, as described in Leutenegger et al. (2006).

The overall normalization and the $G = (f+i)/r$ ratio are explicit fit
parameters, while the diagnostically important $R = f/i$ ratio is a
function of radius, via the radial dependence of the photoexcitation
rate of electrons out of the upper level of the forbidden line into
the upper level of the intercombination line. This physics is con-
trolled in our modelling by the same $R_0$ parameter that describes
the onset radius of X-ray emission. Lower values of $R_0$ give more
plasma close to the photosphere, where it is more strongly affected
by photoexcitation, providing a lower $R \equiv f/i$ value than if $R_0$
were larger and the overall photoexcitation rate were lower. Thus,$R_0$
controls both the linewidths and the relative strengths of the in-
tercombination and forbidden lines in the observed spectrum in a
self-consistent manner. For the photoexcitation modelling, we use
UV fluxes from a TLUSTY $T_{\text{eff}} = 42,500$ K, $\log g = 3.75$ model
atmosphere (Lanz & Hubeny 2003) and the atomic parameters from
Dere et al. (2007).

The number of free parameters in the models – both for the single
lines and for the He-like complexes – is kept to a minimum. We
fix the wind terminal velocity ($v_\infty = 3200$ km s$^{-1}$) and the velocity
law parameter ($\beta = 0.7$) at the value determined from the UV data.

There is an extensive discussion of the sensitivity of the important
model parameters, $\tau_*$ and $R_0$, to these, and other, fixed parameters
as well as the effect of such factors as background subtraction and
continuum placement in section 4.3 of Cohen et al. (2010), to which
we refer the reader.

The results of our wind profile fits to the five lines and line com-
plexes are shown in Fig. 4 for the single Ly$\alpha$ lines and in Fig. 5
for the three He-like line complexes. The quantitative results are
summarized in Table 2. We note that when we increase the wind ve-
celcity parameter, $\beta$, from 0.7 to 1.0, the characteristic optical depth
values, $\tau_*$, increase by roughly 30 per cent, while the onset radii,$R_0$, increase by several tenths of a stellar radius. Similarly, there is
sensitivity of the important derived parameters to the assumed wind
terminal velocity. For a higher terminal velocity of 3400 km s$^{-1}$,
the best-fitting $\tau_*$ values decrease by roughly 20 per cent and in-
crease by the same amount when we use a lower terminal velocity
of 3000 km s$^{-1}$. The onset radii, $R_0$, vary by roughly 10 per cent
for these changes in terminal velocity. We note that these system-
etic uncertainties – especially for $\tau_*$ – are small compared to the
statistical errors.

Before we move on to interpreting these model-fitting results,
we report on a few experiments involving fitting different types of
models to these same emission lines. Specifically, Gaussian profiles
have traditionally been fitted to the broadened emission lines seen in
O stars. Therefore, we fit the highest signal-to-noise ratio single line
in the spectrum, the Mg xi Ly$\alpha$ line, with an unshifted Gaussian.
As expected from the asymmetry seen in the bottom panel of Fig. 4,
the fit is poor (the wind profile fit is preferred at >99.99 per cent).

Allowing the Gaussian centroid to be a free parameter, we find an
improved fit with a large centroid blueshift (to $\lambda = 8.401$ Å), equiv-
alent to $-730 \pm 200$ km s$^{-1}$, and a width of $\sigma = 1200^{+200}_{-170}$ km s$^{-1}$.
This shifted-Gaussian fit is statistically indistinguishable from the
wind profile model fit. Although the windprofile fit is more mean-
ingful, as it is based on a physically realistic model while having
no more free parameters than the Gaussian model, the Gaussian fit
confirms and quantifies the large linewidths and blueshifts expected
from EWS emission.

Along similar lines, He-like complexes can be fitted with three
Gaussians, providing a direct measure of the $f/i$ ratio, from which
a single radius of formation can be inferred. We show these results
in Fig. 6. For the Mg xi complex we find a low ratio of 0.40$^{+0.27}_{-0.17}$.

We next fit the same model, but with the $f/i$ ratio fixed at the ‘low-
density limit’ that would be expected if the X-ray plasma were very
far from the photosphere, where photoexcitation cannot alter the
ratio. This fit (which is also shown in Fig. 6) is poor compared to
the $f/i = 0.4$ fit, implying that the hot plasma is relatively close
to the photosphere. This conclusion is in good agreement with the
result from fitting the three wind profile models (hewind), in which
the onset radius of a distributed source of X-ray-emitting plasma,$R_0$,
is constrained to be within 1 stellar radius of the photosphere.

---

2 The windprofile model’s implementation in XSPEC is described at
https://heasarc.gsfc.nasa.gov/docs/xanadu/xspec/models/windprof.html, as is the
hewind model we use to fit helium-like complexes.
Porosity, due to optically thick clumps, can affect X-ray line profiles by reducing the average optical depth of the wind (Oskinova, Feldmeier & Hamann 2006), and is another effect we might consider when fitting the emission line data. However, the porosity length that is necessary to provide a measurable effect is quite large (Owocki & Cohen 2006) compared to the small-scale structure in state-of-the-art 2D radiation hydrodynamics simulations (Dessart & Owocki 2003, 2005). To explore the effects of porosity on the fit quality and on the other parameters, we fit the Mg xii Lyα line with a model having an effective opacity modified by porosity from spherical clumps. This model is similar to the one described in Owocki & Cohen (2006) – using the same porosity length \( h(r) = \ell f \), where \( \ell \) is the characteristic clump size and \( f \) is the clump filling factor formalism – but here employing a radial clump distribution determined by the wind \( \beta \)-velocity law, as used by Oskinova et al. (2006). We fit the characteristic optical depth at \( \tau_\alpha = 4.2 \), which is the value we would expect at the wavelength of the Mg Lyα line assuming a mass-loss rate of \( 1.8 \times 10^{-5} M_\odot \text{yr}^{-1} \) (Taresch et al. 1997). The fit we obtain is similar in quality to the windprofile fit reported in Table 2. But in order to achieve this good fit, a very large terminal porosity length of \( h_\infty = 5.3 R_\epsilon \) is required (with a 68 per cent lower confidence limit of \( h_\infty = 2.5 R_\epsilon \)), where the radially varying porosity length is given by \( h(r) = h_\infty (1 - R_\epsilon / r)^\beta \). If we use \( 2.6 \times 10^{-5} M_\odot \text{yr}^{-1} \) as the standard, smooth-wind mass-loss rate (Repolust et al. 2004), then the required porosity length is even larger. Even the minimum porosity length of \( h_\infty = 2.5 R_\epsilon \) is inconsistent with the numerical simulations of the LDI (Dessart & Owocki 2003, 2005), requiring, for example, clumps that are individually 0.25\( R_\epsilon \), in scale in a wind with a uniform filling factor of \( f_v = 0.1 \).

### 3.2 Mass-loss rate determination from the line profiles

Given the characteristic optical depth values (\( \tau_\alpha \), listed in Table 2) obtained from fitting each line with the windprofile model, we can derive constraints on the wind mass-loss rate of HD 93129A. The characteristic optical depth is defined as \( \tau_\alpha = \kappa M / 4 \pi R_\epsilon v_\infty \alpha \), so that by assuming a model of the bulk wind’s X-ray opacity, \( \kappa(\lambda) \), as well as a value for the stellar radius and wind terminal velocity, we can fit the wavelength-dependent \( \tau_\alpha \) values with the mass-loss rate as the only free parameter of the fit, as \( M = 4 \pi R_\epsilon v_\infty \tau_\alpha(\lambda) / \kappa(\lambda) \). We have demonstrated this process for analysing the Chandra grating spectrum of the O supergiant \( \zeta \) Pup (Cohen et al. 2010). Because of the lower quality of the Chandra spectrum of HD 93129A compared to that of \( \zeta \) Pup, and because of the much smaller number (5 versus 16) and narrower wavelength range of usable lines, the wavelength trend in \( \tau_\alpha \) is not apparent for HD 93129A. However, the five \( \tau_\alpha \) values are certainly consistent with the expected wavelength trend.

We constructed a model of the bulk wind opacity for HD 93129A, assuming that H and He are fully ionized, and assuming typical values for the ionization balance of metals (generally dominated by triply ionized states). Furthermore, we assume solar abundances from Asplund et al. (2009), except for C, N and O, which are altered by CNO processing, according to the spectral analysis of Taresch et al. (1997). We take the C, N and O values from these authors, but rescale them so that the sum of the abundances of these three elements is equal to the sum of the C, N and O in the Asplund et al. (2009) solar abundances. This effectively gives us \( Z_\text{C} = 0.25 \), \( Z_\text{N} = 3.02 \) and \( Z_\text{O} = 0.47 \), where Asplund et al. (2009) is the solar reference. We should note, however, that because the emission lines we derive \( \tau_\alpha \) values from are all at short wavelengths, the alterations to C, N and O abundances have almost no effect on our results.

Changing the overall metallicity – which we assume to be solar – would have an effect, however. The derived mass loss rate scales inversely with the metallicity.

The result of fitting the \( \tau_\alpha \) values for the mass-loss rate is shown in Fig. 7. The best-fitting mass-loss rate is \( 6.8^{+2.4}_{-1.8} \times 10^{-6} M_\odot \text{yr}^{-1} \),
the same as the X-ray onset radius, \( R \) that assumes each \( \dot{M} \) described. However, we adopt the mass-loss rate derived from our the corresponding synthetic spectra. Stellar parameters were taken factor approach) in the calculations of the occupation numbers and 2005), which accounts for optically thin clumping (using the filling radius, \( R \) wind is assumed to be smooth. Note that this opacity (which scales as \( \dot{M} \)) used the profile with the line-blanketed, non-LTE, unified (photosphere+wind) model atmosphere code FASTWIND (Puls et al. 2005), which accounts for optically thin clumping (using the filling factor approach) in the calculations of the occupation numbers and the corresponding synthetic spectra. Stellar parameters were taken from Repolust et al. (2004), where the observational data also are described. However, we adopt the mass-loss rate derived from our X-ray analysis. We show the data in Fig. 8 along with three models, each with \( M = 7 \times 10^{-6} \text{M}_\odot \text{yr}^{-1} \) and \( \beta = 0.7 \). The best model has a constant \( f_s = 0.08 \) above a radius \( R_\odot = 1.05R_\odot \), below which the wind is assumed to be smooth. Note that this \( R_\odot \) is not necessarily the same as the X-ray onset radius, \( R_\odot \). In fact, this small clumping radius, \( R_\odot \), is necessary to fit the data, as comparison with the model that assumes \( R_\odot = 1.3R_\odot \) in Fig. 8 shows. In that model, the simulated strength of the core is much too low, reflecting the reduced H\( \alpha \) opacity (which scales as \( M^2/\dot{M} \)) in the lower wind. This early onset of wind clumping has been found for a number of other stars as well (Bouret, Lanz & Hillier 2005; Puls et al. 2006). We also note that the simplest case of a spatially constant \( f_s \) actually reproduces using the stellar radius from Repolust et al. (2004). This represents a factor of 3 (Taresch et al. 1997) or 4 (Repolust et al. 2004) reduction with respect to traditional H\( \alpha \)-based determinations that assume a \( \alpha \) factor of 3 (Taresch et al. 1997) or 4 (Repolust et al. 2004) reduction using the stellar radius from Repolust et al. (2004). This represents a constant \( f \) that the simplest case of a spatially constant \( f \) actually reproduces Figure 6. The MEG data for the Mg XI line complex fit with three shifted Gaussians. When the \( f/\ell \) ratio is a free parameter (red), it is low (0.4 \( \pm \) 0.2). When the ratio is fixed at the normal, equilibrium limit \( (f/\ell = 2.7) \) with no photoexcitation, as would be expected far from the star (green), the fit is poor.

\(^a\)Closely spaced doublets in the Ly\( \alpha \) lines and He-like intercombination lines are fitted with a single profile model centred at the emissivity-weighted wavelength of the two components.

\(^b\)For the He-like complexes, the total normalization of all the lines in the complex is indicated.

the H\( \alpha \) data reasonably well for this star, in contrast to, for example, \( \lambda \) Cep, for which a rather strong radial dependence of \( f_s \) is needed (Sundqvist et al. 2011).

3.3 Global thermal modelling

While the individual line profiles provide information about the kinematics of the shock-heated plasma, its spatial distribution and the degree of attenuation by the bulk wind in which the shock-heated plasma is embedded, complementary information is contained in the overall spectral energy distribution. The broad-band spectrum provides information about the temperature distribution of the shock-heated plasma and also about the wind mass-loss rate via the degree of attenuation of the X-rays. Therefore, to complement the spectral modelling of individual emission lines, described in the previous two subsections, we fit global thermal models to the low-resolution zeroth-order spectrum of component A shown in Fig. 2.

The model assumes optically thin, collisional-radiative equilibrium (‘coronal’) emission [vapec, the (Variable abundance) Astrophysical Plasma Emission Code (Smith et al. 2001)]. It is attenuated by the cold, neutral interstellar medium (ISM) (via the xspec model tbabs; Wilms, Allen & McCray 2000) and – for the EWS emission – the partially ionized stellar wind (via the xspec custom model
windtabs; Leutenegger et al. (2010). We model the EWS emission with a single isothermal vapec spectrum. To account for the contribution of harder X-rays from the wind–wind interaction, we include a second thermal emission component attenuated only by the ISM. This composite model is invoked in XSPEC as (vapec × windtabs + vapec) × tbabs. The free parameters of the model include the temperatures of the two vapec components, their emission measures, the characteristic mass column, $\Sigma_\star = \tau_{\gamma}/k$ (g cm$^{-2}$), of the wind absorption model, windtabs, and the interstellar column density. Fixed parameters include the metallicity (fixed at solar, except for CNO) of the emission model and the wind velocity profile (described by $\beta = 0.7$) of the wind attenuation model. We note that the windtabs model (Leutenegger et al. 2010) has two features that make it distinct from interstellar attenuation models and make it more appropriate for the modelling attenuation by a stellar wind with embedded shocks: (1) it incorporates atomic cross-sections from partially ionized species (e.g. $\text{O}^{++}$ rather than neutral $\text{O}$) and assumes that $\text{H}$ and $\text{He}$ are fully ionized and (2) it uses an exact radiation transport model appropriate to an emitter spatially distributed within the absorbing medium. Leutenegger et al. (2010) show that the attenuation from this realistic wind transport model differs significantly from the exponential (‘slab’) attenuation implemented in ISM absorption models (their figs 5 and 8). For the fitting we report on here, we use a solar abundance (Asplund et al. 2009) wind opacity model, but with altered C, N and O abundances according to Taresch et al. (1997), just as we did for the analysis of the ensemble of $\tau_{\gamma}$ values discussed in the previous subsection. The vapec emission model assumes the same abundances as the windtabs absorption model.

We fit the above-described composite thermal emission with wind plus ISM absorption model to the zeroth-order spectrum extracted from the seven co-added pointings. This low-resolution CCD spectrum has significantly better signal-to-noise ratio than the dispersed grating spectra, but at a resolving power $\langle E/\Delta E \rangle$ of only a few tens. It extends to lower energies (0.5 keV) than the dispersed spectrum effectively does. The zeroth-order spectrum does not suffer from significant pile-up effects (unlike bare ACIS observations of the same star). We use $\chi^2$ as the goodness of fit statistic and put confidence limits on the fitted model parameters using the $\Delta \chi^2$ formalism of Press et al. (2007).

We let the interstellar column density be a free parameter of the fit, and found a best-fitting value of $N_{\text{H}} = 4.1 \times 10^{21}$ cm$^{-2}$, which is very close to the value implied by the colour excess ($N_{\text{H}} = 3.7 \times 10^{21}$ cm$^{-2}$; Gagné et al. 2011). The 68 per cent confidence limits for $N_{\text{H}}$ (ISM) extend from $3.5 \times 10^{21}$ to $5.0 \times 10^{21}$ cm$^{-2}$. The best-fitting model has emission component temperatures of $kT = 0.61 \pm 0.02$ and 3.11$^{+0.11}_{-0.09}$ keV, where the hotter component has only 6 per cent of the total emission measure. We conjecture that this hotter component represents a small amount of CWS X-ray emission, presumably associated with the non-thermal radio emission detected in the system (Benaglia et al. 2006). Its contribution is negligible below photon energies of 2.5 keV. This provides further confirmation that the wind–wind X-rays do not affect the line profiles we discussed in the previous subsection.

The characteristic wind mass column density, $\Sigma_\star$, in the windtabs model, is found to be $\Sigma_\star = 0.0522^{+0.0049}_{-0.0045}$ g cm$^{-2}$. Using the wind terminal velocity and stellar radius from Repolust et al. (2004), this corresponds to a mass-loss rate of $M = 5.18^{+1.83}_{-1.45} \times 10^{-5}$ M$\odot$ yr$^{-1}$. The biggest contribution to the uncertainty on the wind mass column density is the uncertainty on the interstellar absorption. The quality of the fit is good, with a reduced $\chi^2$ of 1.01 for 113 degrees of freedom. It is shown in Fig. 9.

We note the consistency of the broad-band mass-loss rate determination with the independent determination from the ensemble of line-profile shapes, discussed in the previous subsection. The wind attenuation is significant, as we show in Fig. 9, where we also include a model without wind attenuation. The X-ray luminosity (corrected for ISM attenuation) of the best-fitting model is $L_X = 7.29 \times 10^{33}$ erg s$^{-1}$ (giving $L_X/L_{\text{bol}} = 1.3 \times 10^{-5}$), but when we also correct for wind attenuation, we find $L_X = 3.30 \times 10^{33}$ erg s$^{-1}$. This implies that 78 per cent of the X-ray emission above 0.5 keV produced by EWSs is absorbed before it escapes the wind (which can be seen graphically in the inset of Fig. 9). Note that nearly all of the X-ray emission below 0.5 keV will also be attenuated.

To further test the plasma emission temperature result, we can examine the temperature-sensitive iron $L$-shell line complexes in the 10–17 Å wavelength range of the grating spectrometer. The data do not have good signal-to-noise ratio in that wavelength region and likely also suffer from modest contamination by dispersed photons from HD 93129B, as we discussed in Section 2. The contamination was primarily a concern with respect to the emission-line shapes.

When we fix the ISM column density at $N_{\text{H}} = 2.5 \times 10^{21}$ cm$^{-2}$ (Taresch et al. 1997), the wind mass column density, and along with it, the mass-loss rate, increases by a factor of 1.8.

Absorption renders the iron line complex near 17 Å undetected.

---

3 This model is also described on the windprofile custom model page on the xspec site.

4 Although the temperature distribution of the shocked plasma is certainly more complex than two discrete temperatures, we find that adding more temperature components does not improve the fit quality.

5 When we fix the ISM column density at $N_{\text{H}} = 2.5 \times 10^{21}$ cm$^{-2}$ (Taresch et al. 1997), the wind mass column density, and along with it, the mass-loss rate, increases by a factor of 1.8.

6 Absorption renders the iron line complex near 17 Å undetected.
value found in our global fitting reported on earlier in this subsection and fixed the interstellar column density at $N_H = 3.7 \times 10^{22}$ cm$^{-2}$.

Because of the large number of charge states with closely spaced ionization energies, Fe L-shell emission is a sensitive diagnostic of plasma temperature (Behar, Cottam & Kahn 2001). Ne-like Fe XVII, with strong emission lines near 15 and 17 Å, is present over a moderately wide range of temperatures, and dominates over the higher charge states. Thus, the dominant plasma temperature is constrained to be about 0.6 keV or lower, while only very small contributions from higher temperatures are compatible with the data.

In Fig. 10 we show the binned MEG data along with the best-fitting thermal emission model, which has a temperature of $kT = 0.3$ keV, in very good agreement with the zeroth-order spectral fitting. Here, though, we can see which specific lines are and are not contributing to the observed flux. The inset figure shows the same data with a model identical to the best-fitting model, except that the wind absorption ($\Sigma_w$, in windtabs) is zeroed out. This model spectrum makes the significance of the wind absorption effect quite obvious. Nearly 80 per cent of the emitted EWS X-rays are absorbed before they can escape from the wind.

3.4 HD 93129B

The zeroth-order spectrum of HD 93129B, the O3.5 companion at a separation of 2.7 arcsec, is shown in Fig. 2. We have also fitted it with a thermal emission model with both wind and ISM absorption (but no CWS component), much as we did for HD 93129A. Because of the low signal-to-noise ratio of this spectrum, we held the interstellar column density fixed at $N_H = 3.7 \times 10^{22}$ cm$^{-2}$, corresponding to the measured colour excess. Our best-fitting model has a temperature of $kT = 0.31 \pm 0.06$ keV and a wind absorption mass column of $\Sigma_w = 0.0221^{+0.0267}_{-0.0215}$ g cm$^{-2}$, corresponding to a mass-loss rate of $M \approx 1 \times 10^{-6} M_\odot$ yr$^{-1}$, with a factor of 2 uncertainty.

We note that this source emission temperature is somewhat lower than that reported in Nazé et al. (2011). This is most likely due to our inclusion of wind absorption, which hardens the emergent spectrum. The ISM-corrected X-ray luminosity of our best-fitting model is $L_X = 1.5 \times 10^{32}$ erg s$^{-1}$, corresponding to $L_X/L_{bol} = 1.2 \times 10^{-7}$, very similar to the value we find for component A.

4 DISCUSSION

The Chandra observations of HD 93129A are consistent with the EWS scenario that is generally assumed to apply to all O stars. The X-ray luminosity is $L_X = 1.3 \times 10^{32} L_{bol}$; very much in line with the canonical value for O star wind-shock sources (Pallavicini et al. 1981), although it is roughly a factor of 2 higher than the average value found for O stars in Carina (Nazé et al. 2011). The emission temperature is quite low (0.6 keV), as is expected from the EWS mechanism, although there is evidence for a small ($\sim$0.02 per cent) contribution from hotter plasma (3.3 keV). The presence of this hotter component is not surprising, given the detection of non-thermal radio emission from the system, presumably associated with CWS involving components Aa and Ab, separated by roughly 100 au. But we stress that the colliding-wind contribution to the overall X-ray spectrum is minimal.

Although the EWS emission temperature of 0.6 keV is low, the overall spectrum is relatively hard. We have shown here, using both the individual line profiles and also the broad-band, low-resolution CCD spectrum, that this is due to attenuation by the star’s dense stellar wind. The two different, largely independent, manifestations of the wind attenuation lead to consistent mass-loss rate
determinations of between 4.7 and $7.0 \times 10^{-6} \, M_\odot \, yr^{-1}$, which represent a factor of several reduction in the mass-loss rate over traditional values determined from density-squared diagnostics. As both X-ray mass-loss rate diagnostics are insensitive to density-squared effects, and because some clumping is certainly expected in the wind of HD 93129A (Lépine & Moffat 2008), the new, lower mass-loss rate seems quite reasonable, and is in line with the factor of 3 mass-loss rate reduction seen in $\zeta$ Pup (Puls et al. 2006; Cohen et al. 2010). This is verified by our modelling of the H$\alpha$ line, which shows that $M = 7 \times 10^{-6} \, M_\odot \, yr^{-1}$ provides a good fit if a constant clump volume filling factor $f_c = 0.08$ is assumed. To explain the strong core of the H$\alpha$ line, a clump onset radius of $R_o = 1.05 R_\star$, also must be assumed. We note that the X-rays are not produced at radii this small. Presumably the wind shocks associated with clumps at the slow-moving base of the wind are not strong enough to produce X-rays.

The kinematics of the X-ray-emitting plasma in HD 93129A determined from the linewidths are consistent with the terminal velocity of the bulk wind ($v_\infty = 3200 \, km \, s^{-1}$), assuming a constant X-ray filling factor above some onset radius, $R_o$. We derive $R_o$ values for each line or line complex from the profile fitting, and find onset radii that are somewhat lower than, but still statistically consistent with, the typical value of $R_o \sim 1.5 R_\star$ from numerical simulations of the LDI (Owocki et al. 1988; Feldmeier et al. 1997; Runacres & Owocki 2002). However, if the wind terminal velocity is lower than we assumed for our fitting, then the $R_o$ values would increase by 0.1 or 0.2, to $R_o \sim 1.5 R_\star$ (for an assumed $v_\infty = 3000 \, km \, s^{-1}$).

The location of the X-ray plasma is further constrained by the forbidden-to-intercombination line ratios in the helium-like line complexes observed in the grating spectra. Using a model that includes both the broadening and attenuation effects on the line profiles in conjunction with the altered forbidden-to-intercombination line ratios due to UV photoexcitation, we find that all three helium-like line complexes are completely consistent with the X-ray-emitting plasma being distributed throughout the wind of HD 93129A, starting at a height of only several tenths of a stellar radius above the photosphere. Using a simpler model where we fit the forbidden-to-intercombination line ratio directly, using Gaussian profiles, we find low $f/ii$ ratios for the Si xi and the Mg xi complexes. For both these complexes, the ratio expected if photoexcitation is unimportant, as would be the case in a binary wind–wind collision zone far from either star’s photosphere, is ruled out with a greater than 95 per cent confidence.

Finally, we must discuss alternative interpretations of the spectra and, especially, the spectral lines. The profiles, while skewed and blueshifted, are not as asymmetric as expected given the very high mass-loss rate traditionally found for the star. Our interpretation is that this is due to an actual mass-loss rate that is modestly lower than the traditional value, but in principle, it could also be due to porosity associated with optically thick and presumably large-scale wind clumping. However, not only are the required porosity lengths very high, but the same clumps that would need to be invoked to generate a porosity effect would also lead to a mass-loss rate reduction due to their effect on density-squared diagnostics. If, for example, the required porosity lengths were achieved with clumps having a size scale of $0.25 R_\star$ and a uniform filling factor of $f_c = 0.1$ in the context of an H$\alpha$ mass-loss rate of $M = 1.8 \times 10^{-5} \, M_\odot \, yr^{-1}$ that assumes no clumping (Taresch et al. 1997), then the filling factor alone, via its effect on the density-squared mass-loss rate, would reduce the mass-loss rate inferred from the H$\alpha$ to a value consistent with what we find from the X-rays without having to invoke any porosity – as we have shown at the end of Section 3.2 and in Fig. 8. Any additional effect from porosity would make the mass-loss rates too low and the X-ray line profiles too symmetric.

5 CONCLUSIONS

We have shown that the Chandra grating spectrum of the extreme O star, HD 93129A, can be understood using the same paradigm that explains the canonical EWS source, $\zeta$ Pup, once adjustments are made for its larger wind terminal velocity and mass-loss rate. Specifically, the kinematics of the X-ray-emitting plasma are consistent with shocks embedded in a $\beta = 0.7$, $v_\infty = 3200 \, km \, s^{-1}$ wind starting at several tenths $R_\star$, and the attenuation signatures in the line profiles are consistent with a mass-loss rate of $4.7 \times 10^{-6}$–$7.0 \times 10^{-6} \, M_\odot \, yr^{-1}$, representing a modest reduction compared to traditional mass-loss rates determined from H$\alpha$ measurements that ignore the effects of clumping, and showing consistency with H$\alpha$ modelling that includes modest clumping, in line with what is seen in LDI simulations (Dessart & Owocki 2005). This mass-loss rate reduction of a factor of 3–4 is consistent with that found for $\zeta$ Pup (Cohen et al. 2010). We have also demonstrated for the first time that modelling wind absorption of X-rays for both line profiles and for the broad-band spectral energy distribution leads to consistent results when a physically realistic model of the broad-band wind attenuation (Leutenegger et al. 2010) is used.

The global spectral modelling indicates that the dominant thermal emission component has quite a modest temperature, of roughly 0.6 keV, as predicted by EWS models. The observed overall hardness of the spectrum is attributable to wind attenuation, rather than high plasma temperatures. The low dominant plasma temperature is also manifest in the low Si xiv/Si xii ratio, which is consistent with the value found in the Chandra grating spectrum of $\zeta$ Pup. There is likely a small amount of hard X-ray emission from colliding-wind binary interaction between components Aa and Ab, many tens of au from either star’s photosphere. Because of the large separation of the components, this X-ray emission makes a small contribution to the overall X-ray spectral properties, representing less than 10 per cent of the system’s X-ray luminosity. The helium-like $f/ii$ ratios also provide evidence that the bulk of the X-rays arise in EWSs.

As HD 93129A is the earliest O star known, and has one of the strongest winds of any O star, the work presented here strongly suggests that the EWS scenario, as described by numerical simulations of the LDI, is widely applicable to O stars, even those with extremely strong winds. X-ray line-profile analysis, especially in conjunction with broad-band spectral modelling, provides a good means of making a clumping-independent mass-loss rate determination for O stars with dense winds.
